

## Objectives:

To determine if looming-sensitive neurons in the locust are able to respond to repeated approaches of multiple visual stimuli that vary in trajectory or size.

## Background:

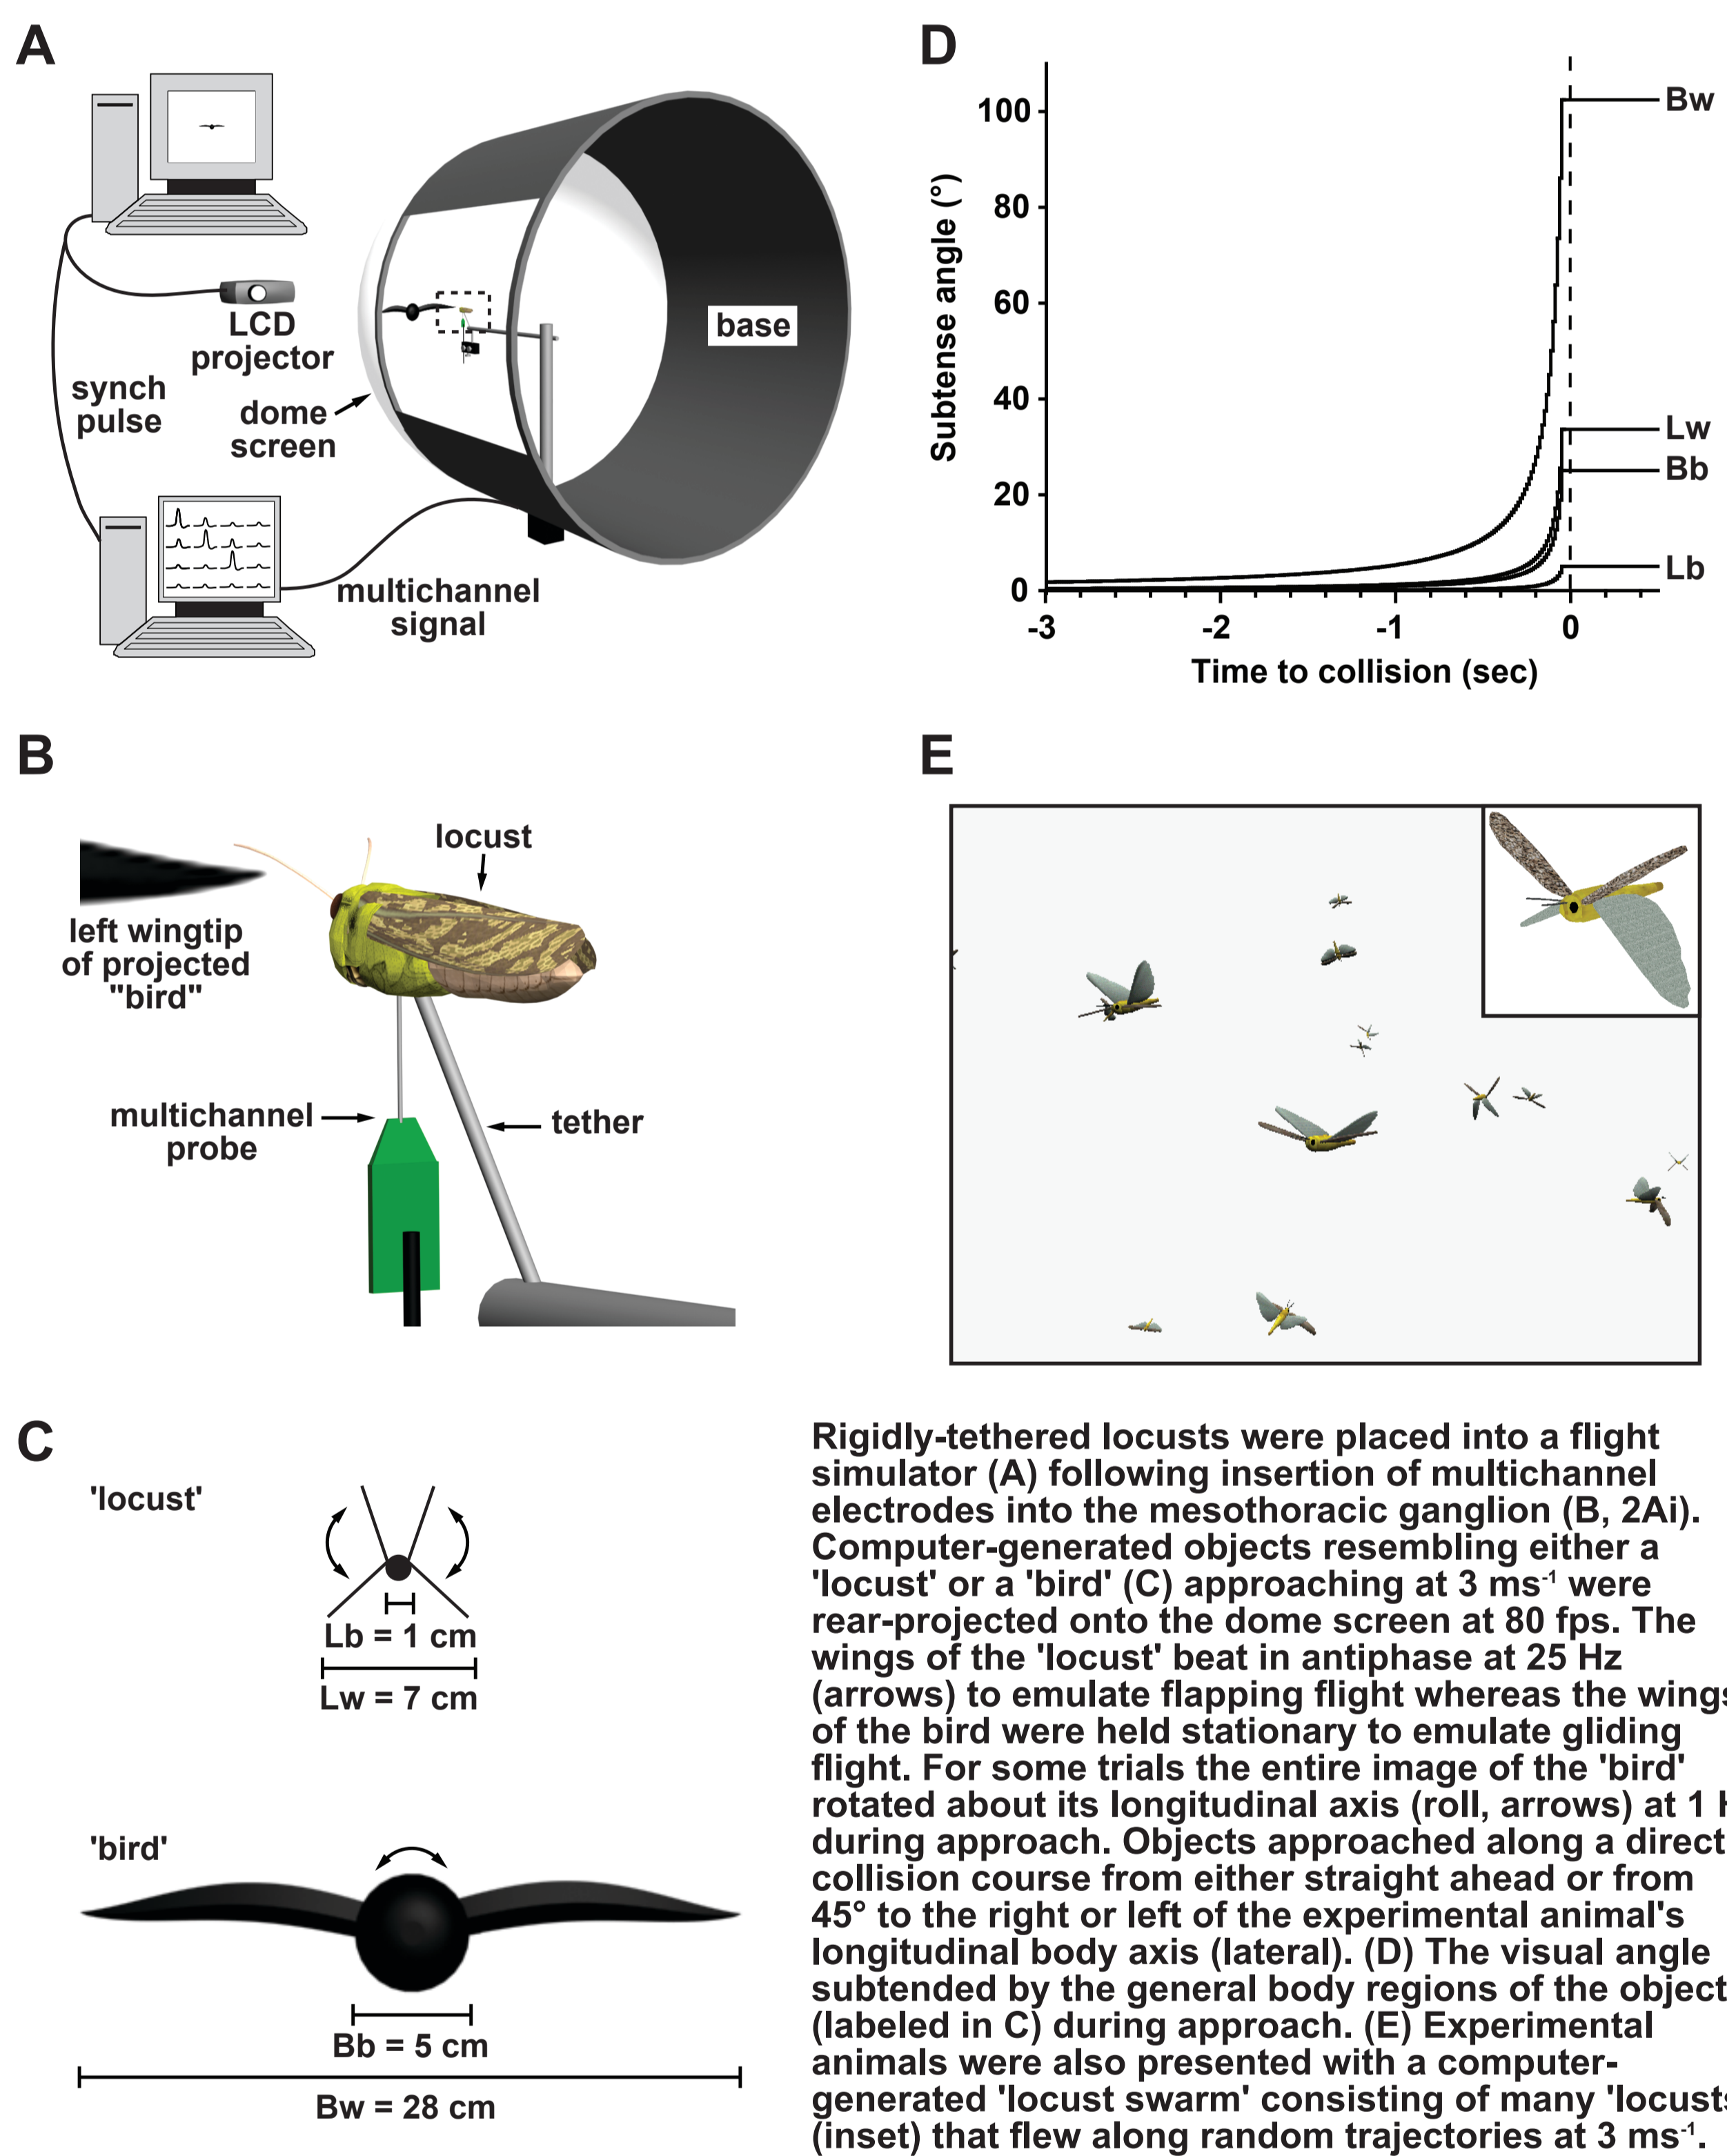

To produce adaptive behaviours animals must be able to remain vigilant to multiple objects in their environment that produce a range of spatiotemporal properties. For example, survival depends on the ability to distinguish between conspecifics and potential predators.

In the locust the Lateral Giant Movement Detector (LGMD) integrates visual input from the compound eyes and transfers information about looming stimuli<sup>1,2,3</sup> in a 1:1 spike ratio, to the Descending Contralateral Movement Detector (DCMD)<sup>4</sup>. The DCMD descends to the thoracic ganglia to make synaptic connections to interneurons and motoneurons that control the legs and wings<sup>5,6,7,8</sup>. Thus the LGMD/DCMD complex is an excellent model system to study mechanisms of how an animal is able to extract information about ecologically-relevant visual stimuli.

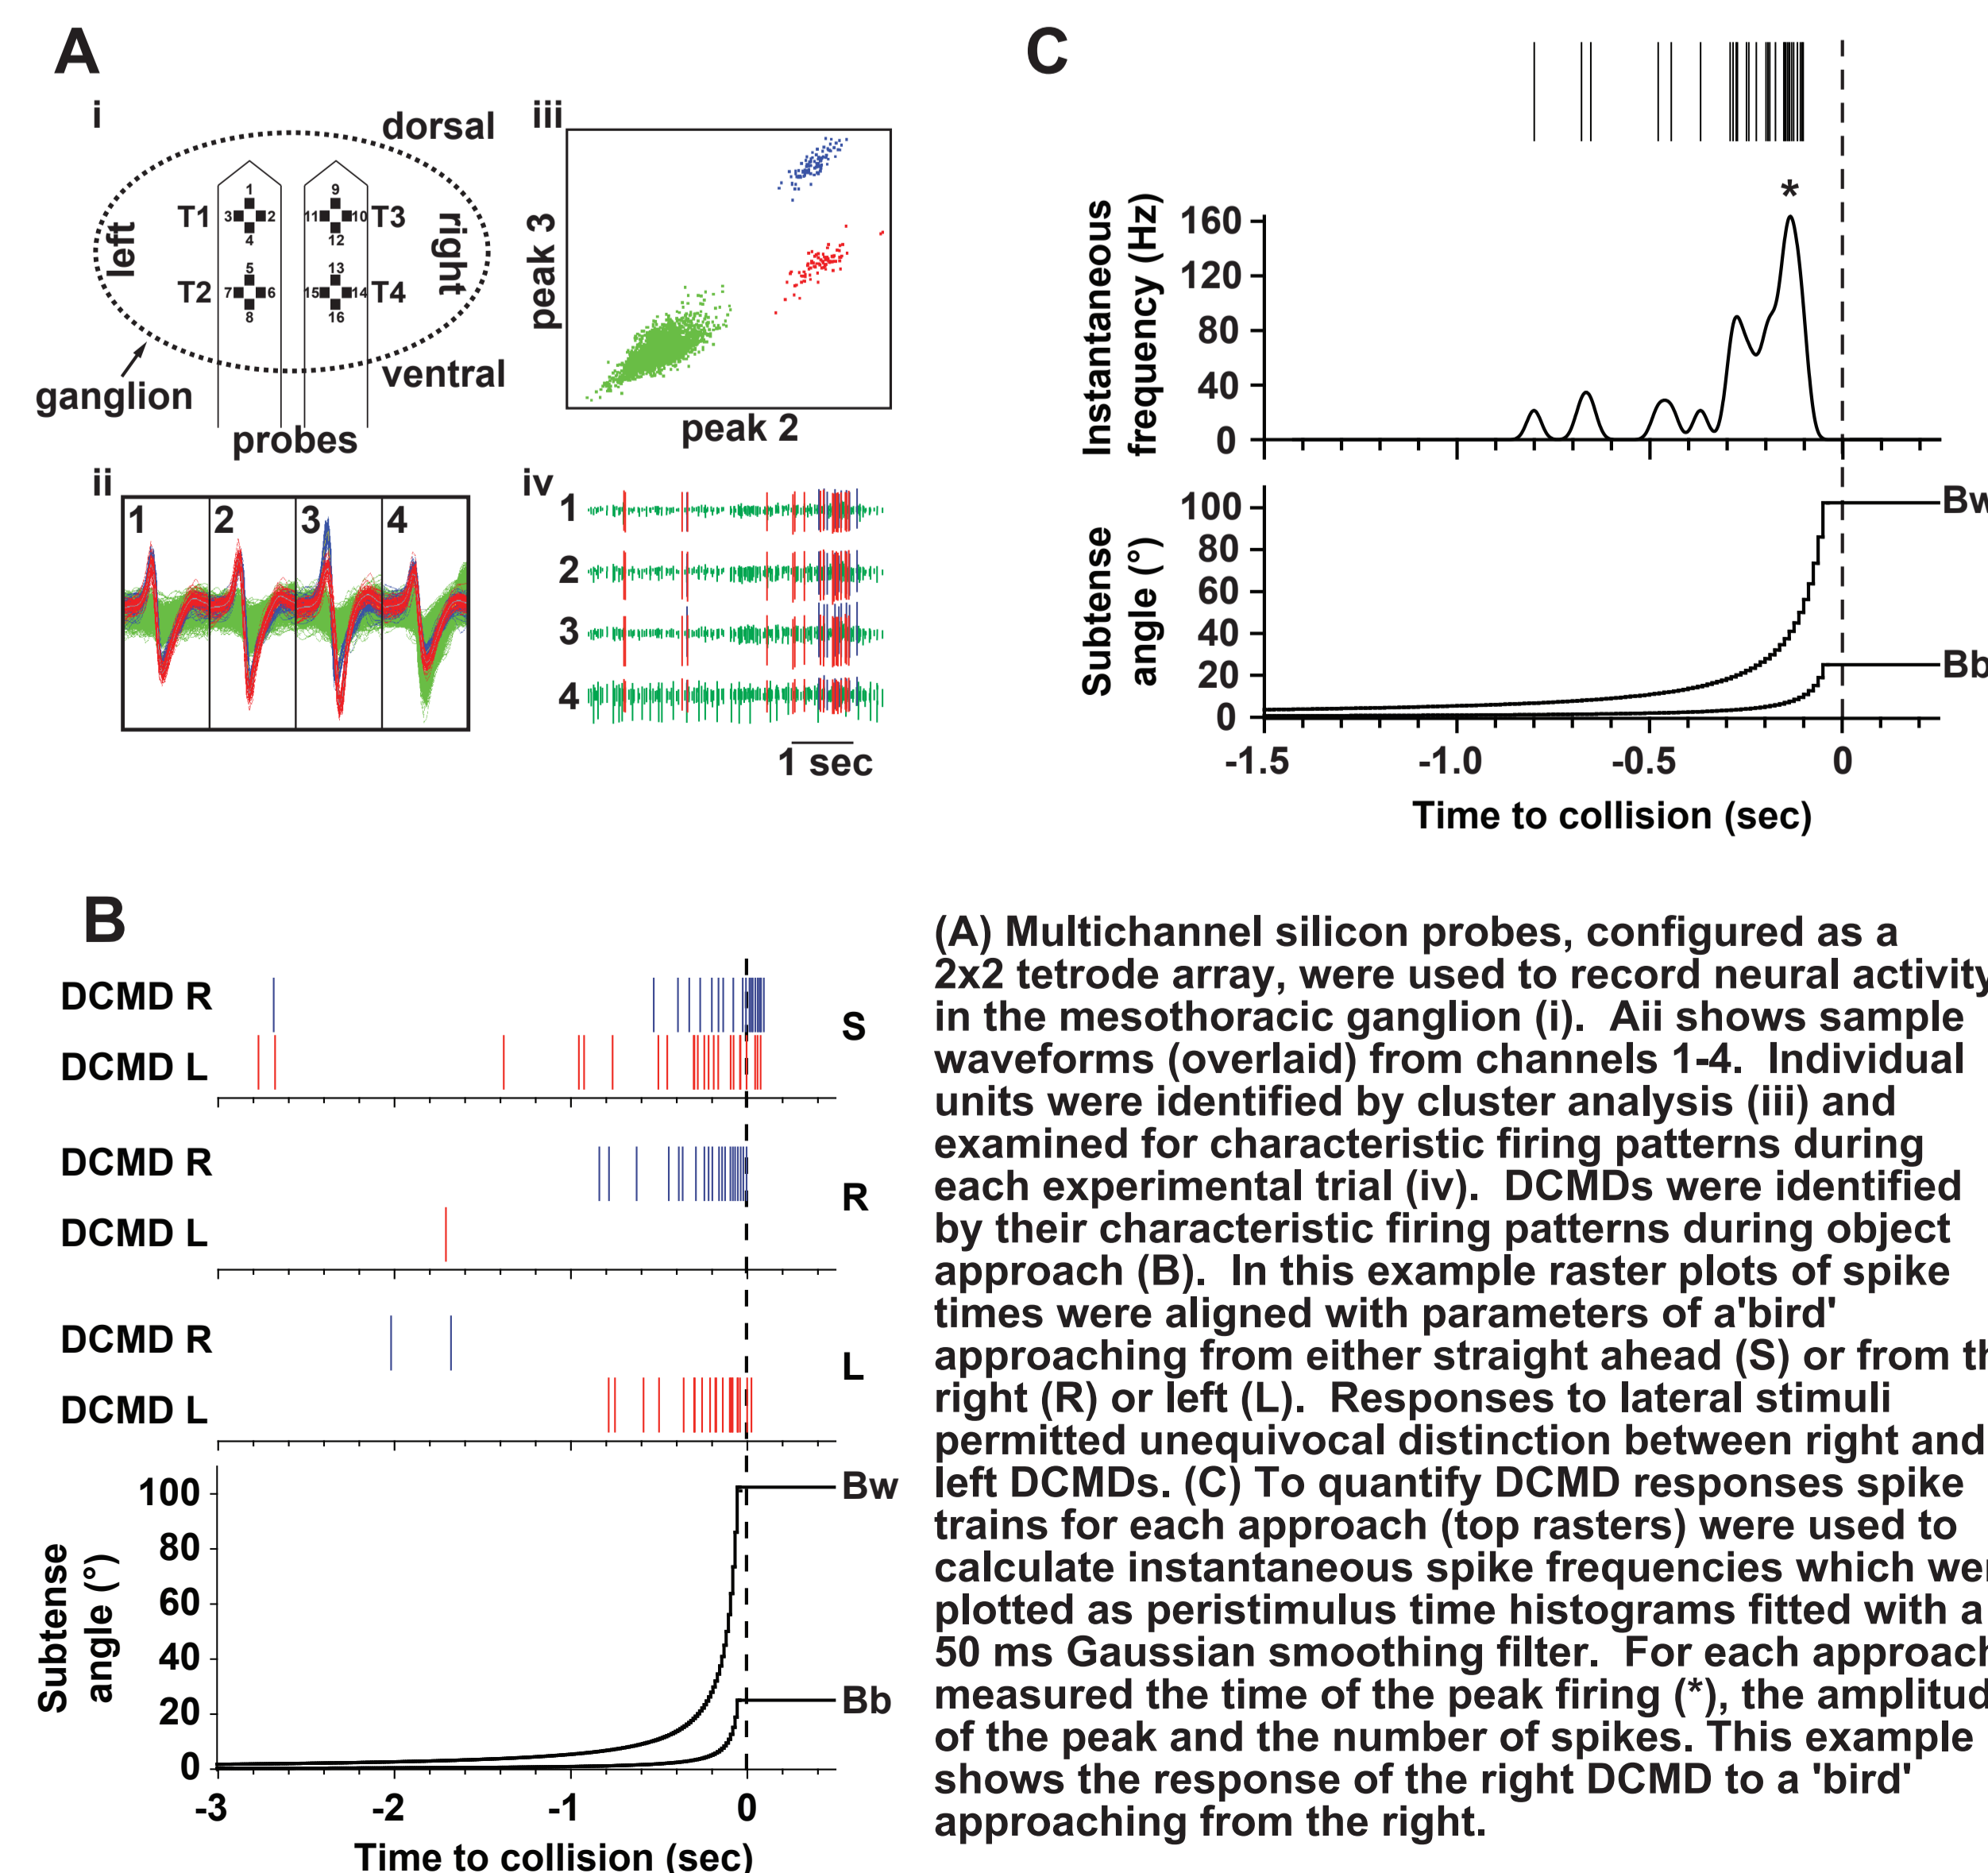

The DCMDs of gregarious locusts are resistant to habituation of repeated presentations of a looming object<sup>9</sup> which could permit effective flight within a swarm. However, there is little information on how the DCMDs respond to visual stimuli that emulate objects that the locust may encounter in the real world.

The experiments described here were designed to describe the responses of the DCMDs to objects that emulate the approach of a conspecific and a potential predator (a 'bird'). Moreover, the experiments address 2 main questions: 1) how do habituated DCMDs respond to objects approaching along a new trajectory or to a new object size? 2) how do the DCMDs respond to multiple objects on random trajectories, as might be expected in a locust swarm?

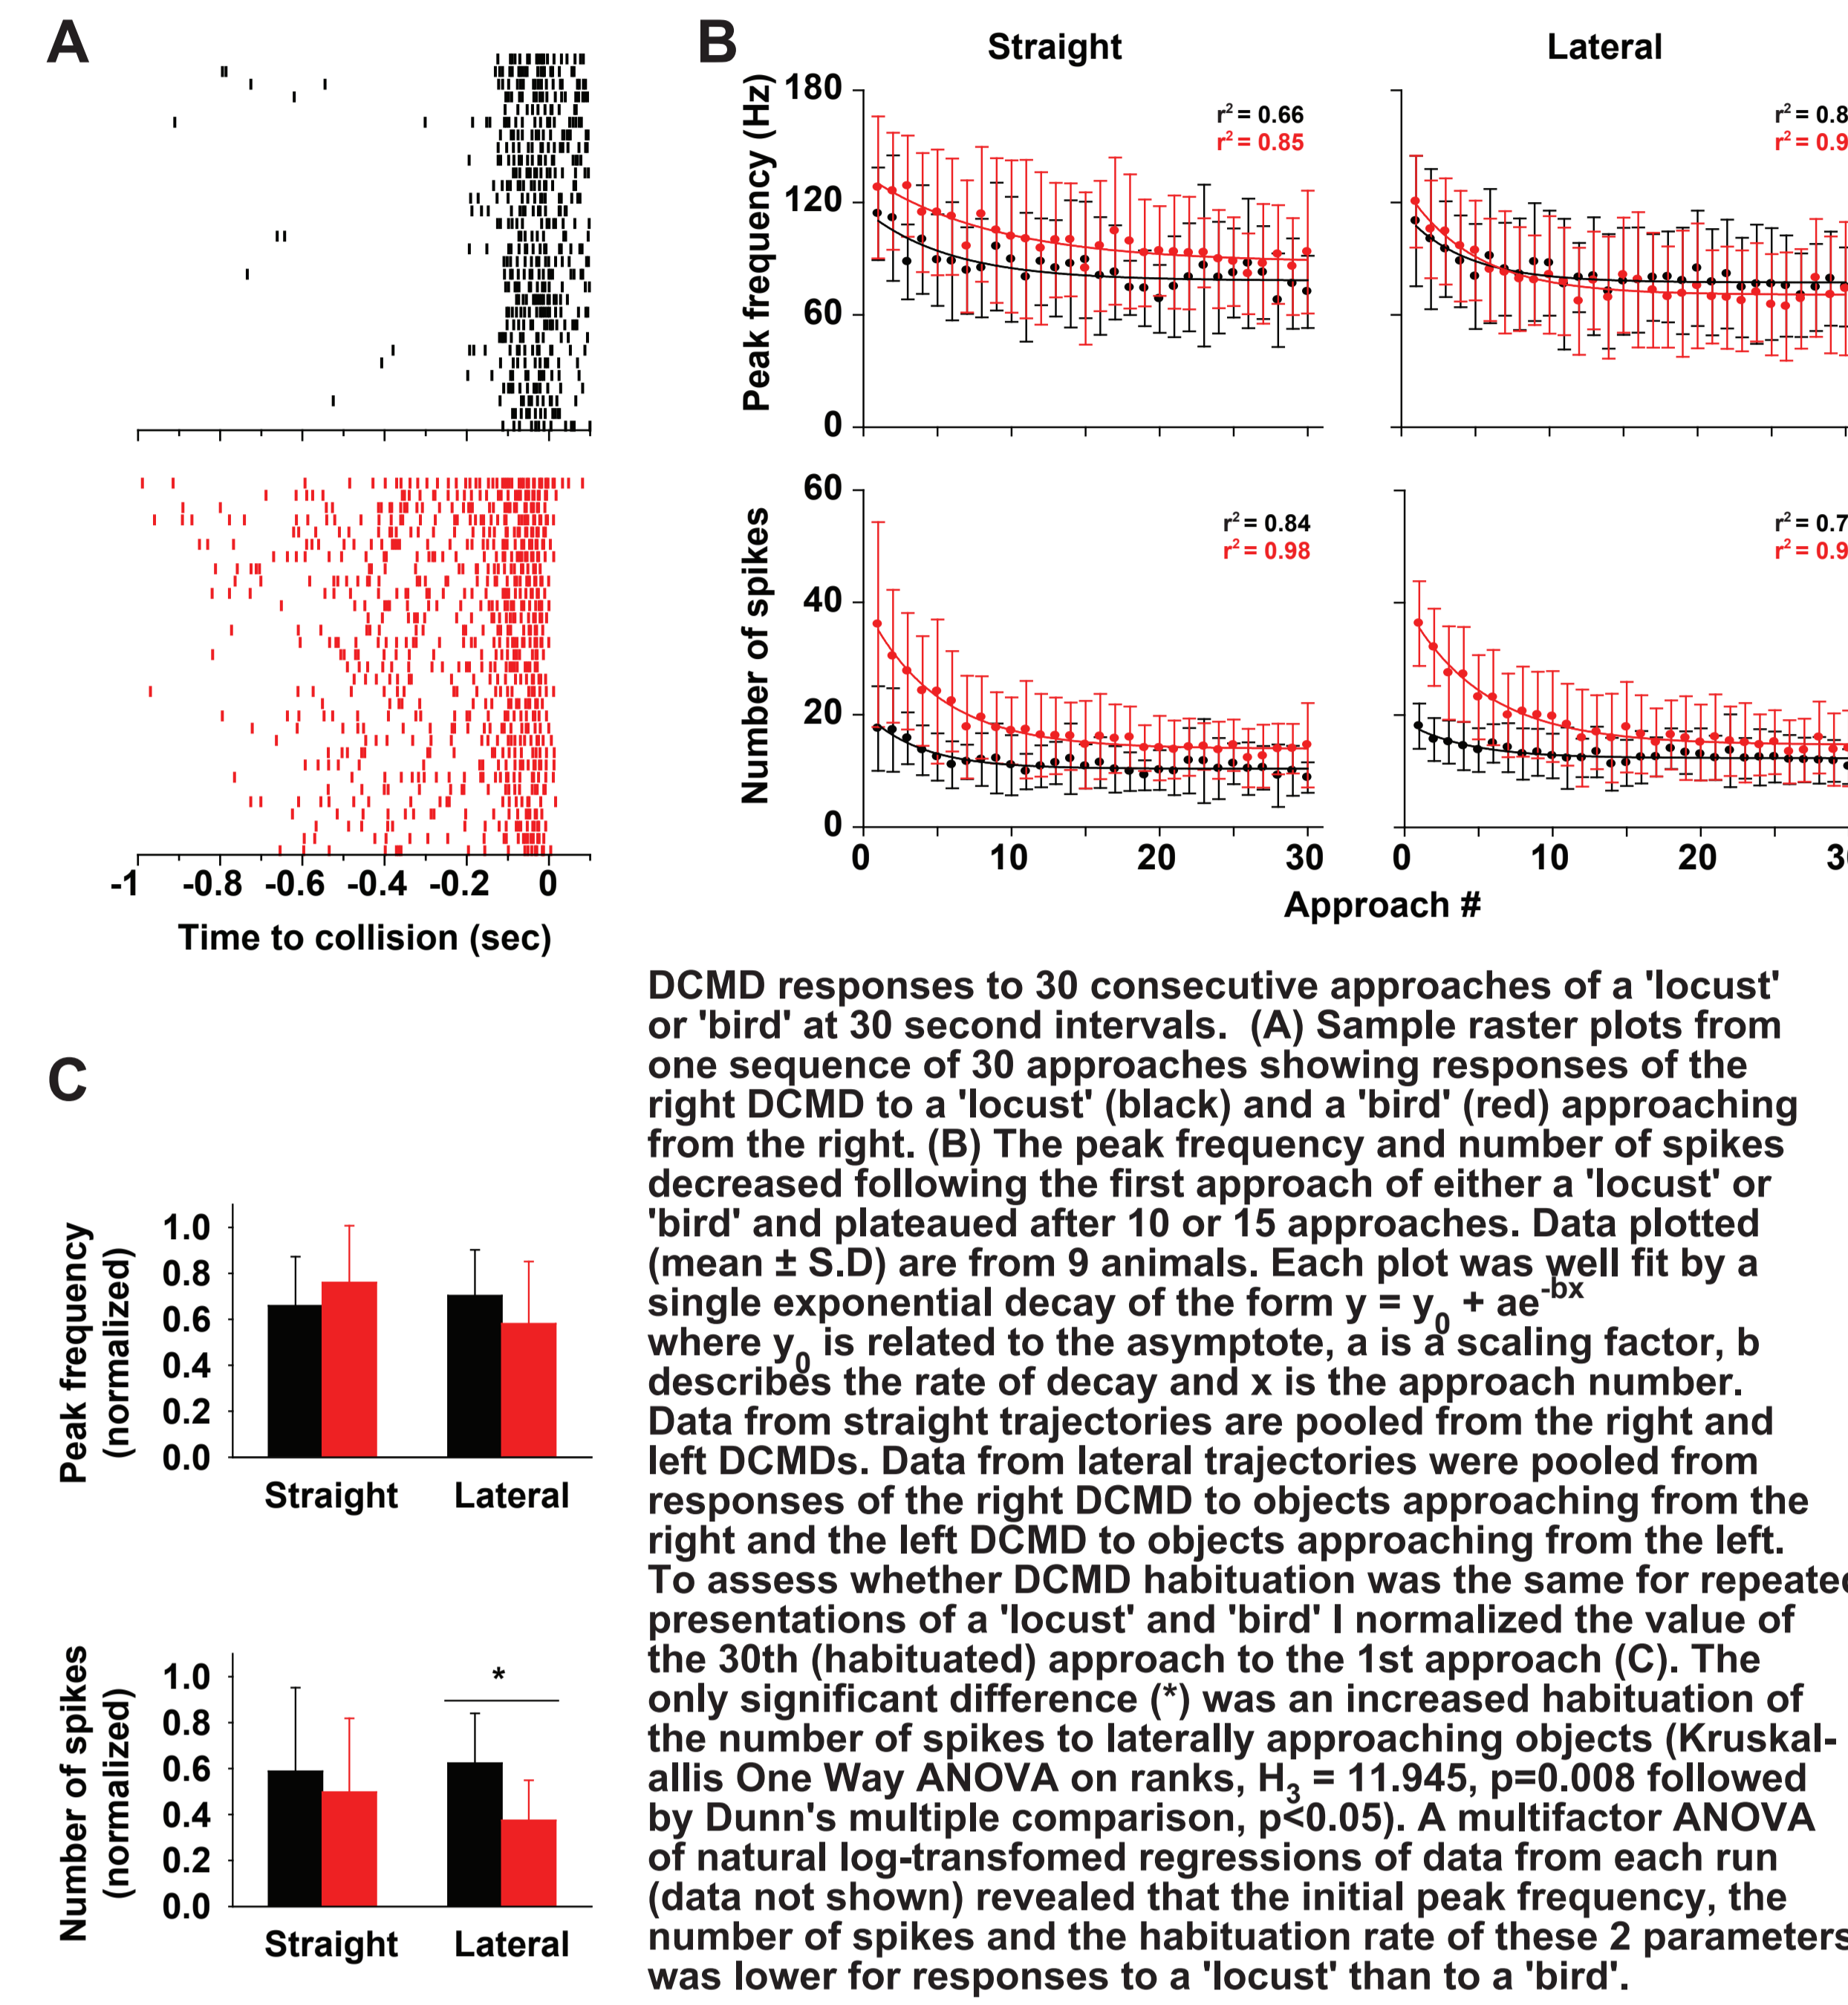

## 1 Experimental setup

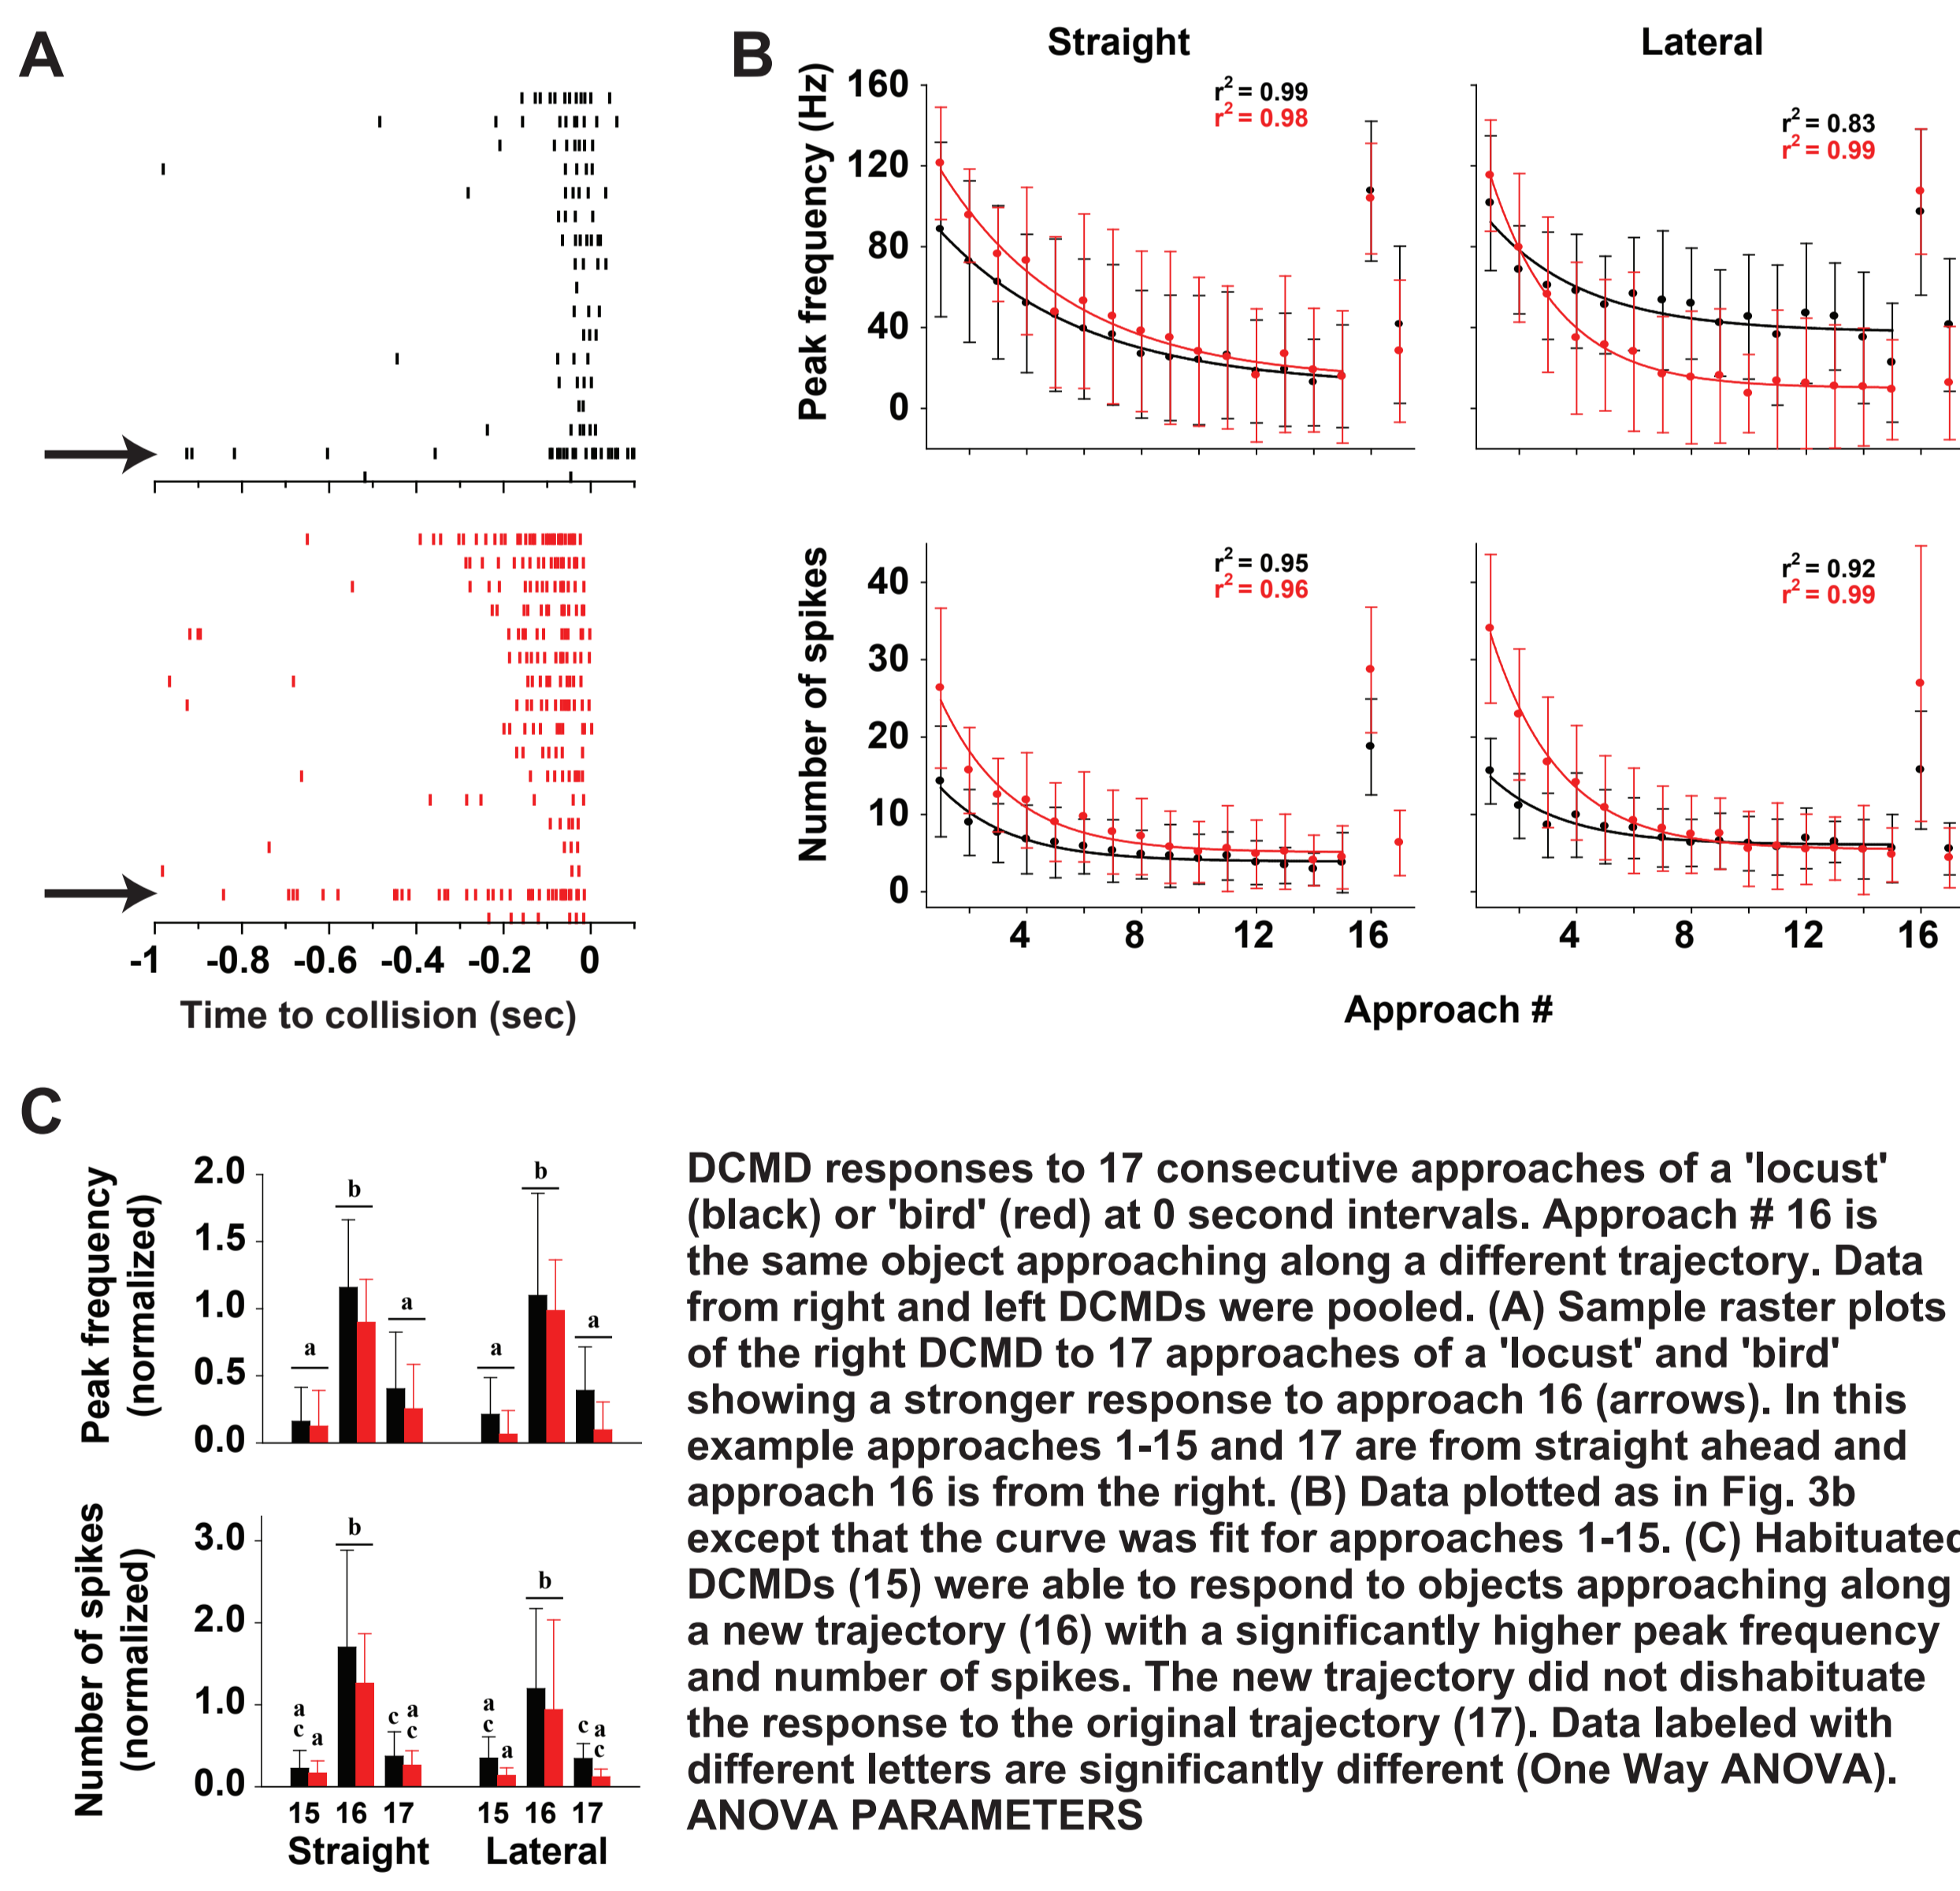

## 2 DCMD recordings

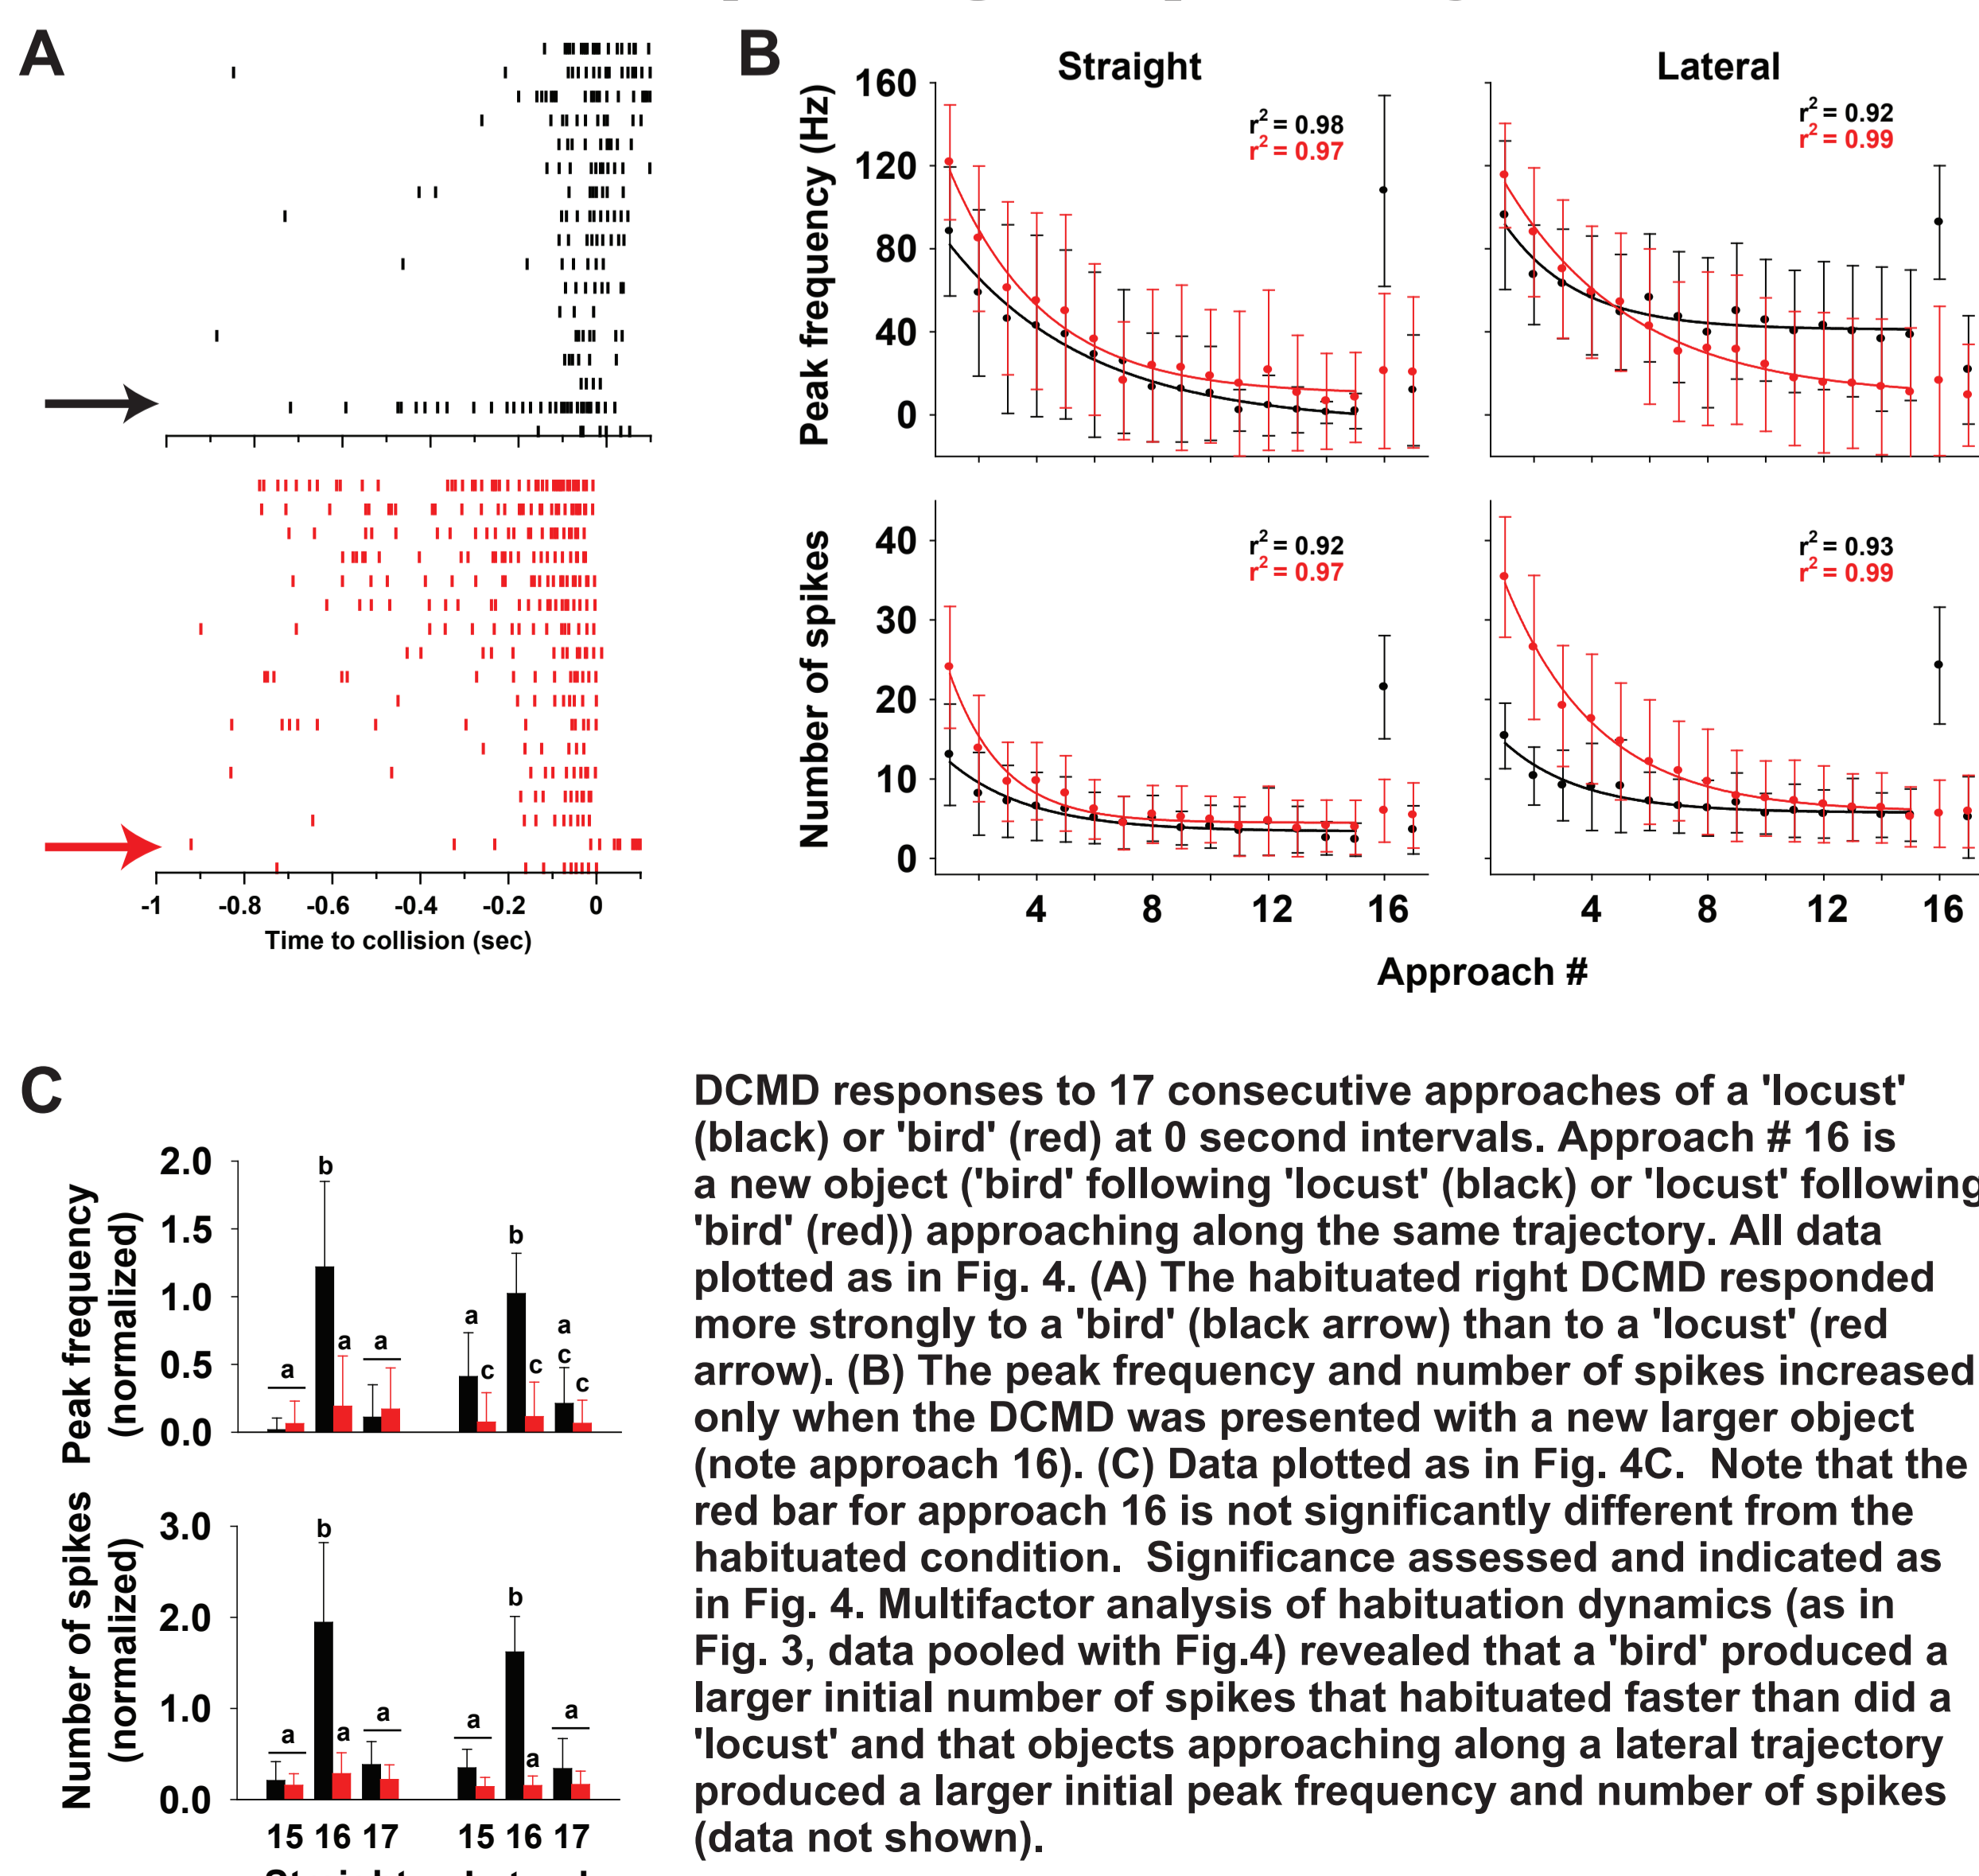

## 3 Habituation of DCMD responses

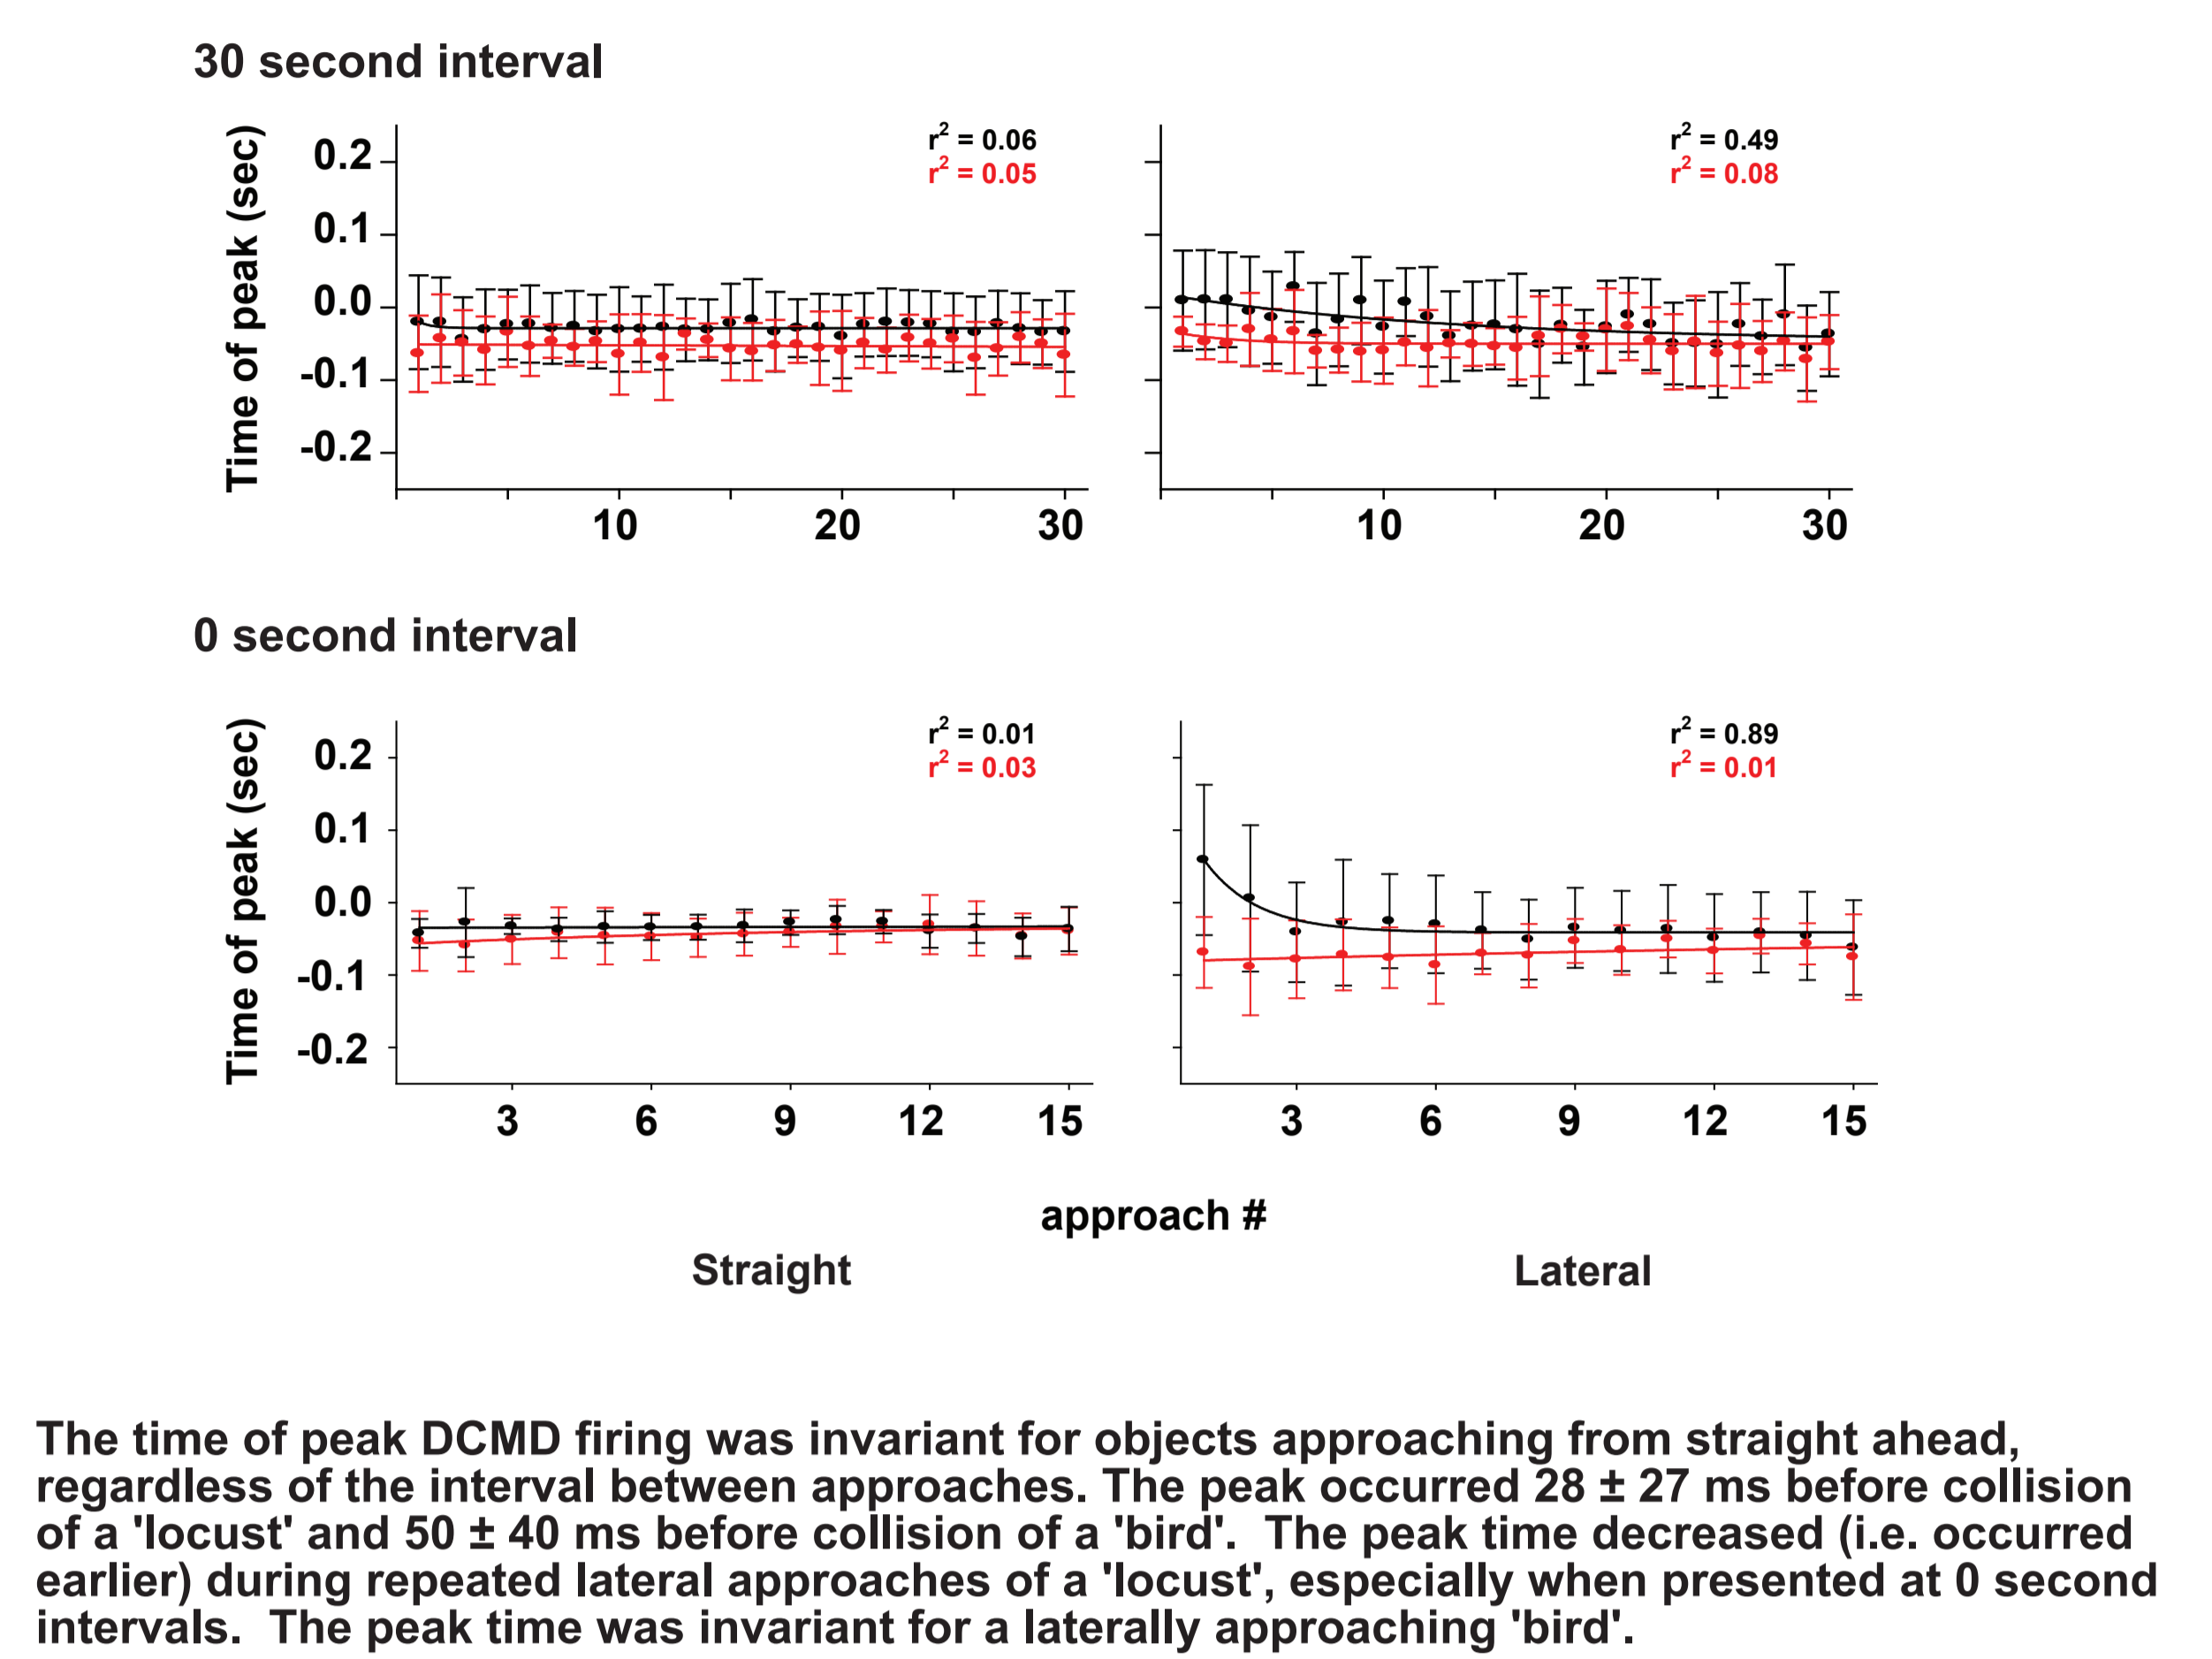

## 4 Maintained sensitivity to a new object trajectory

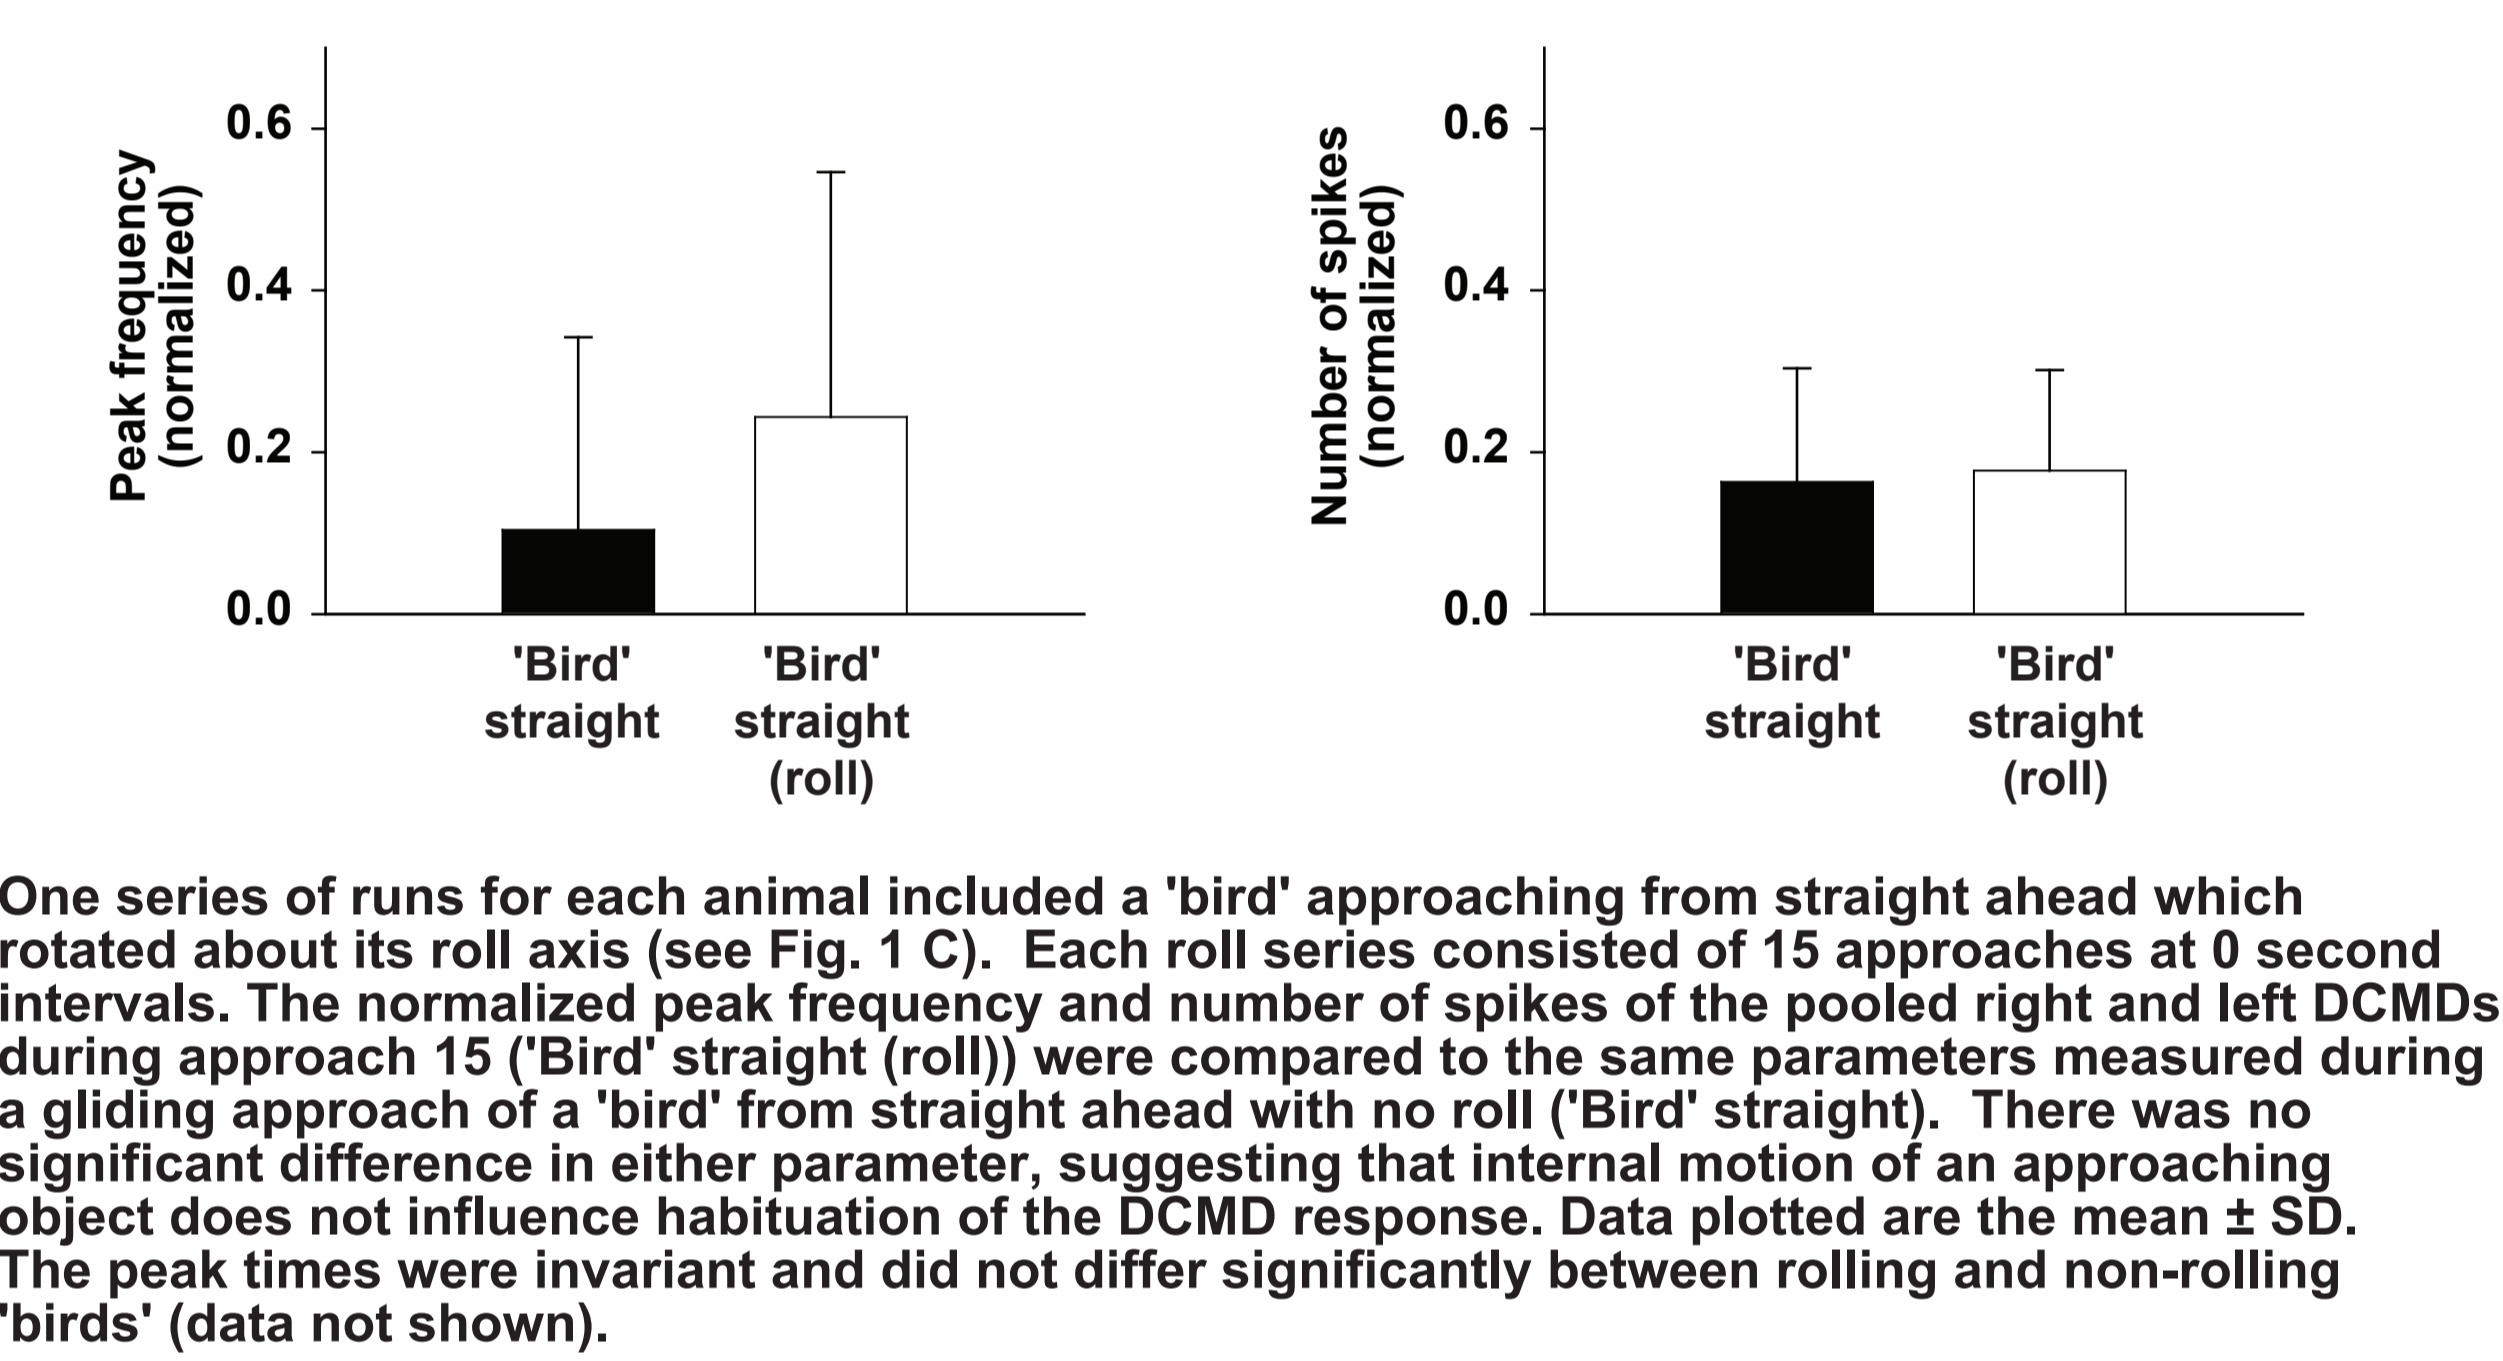

## 5 Maintained sensitivity to a new (larger) object

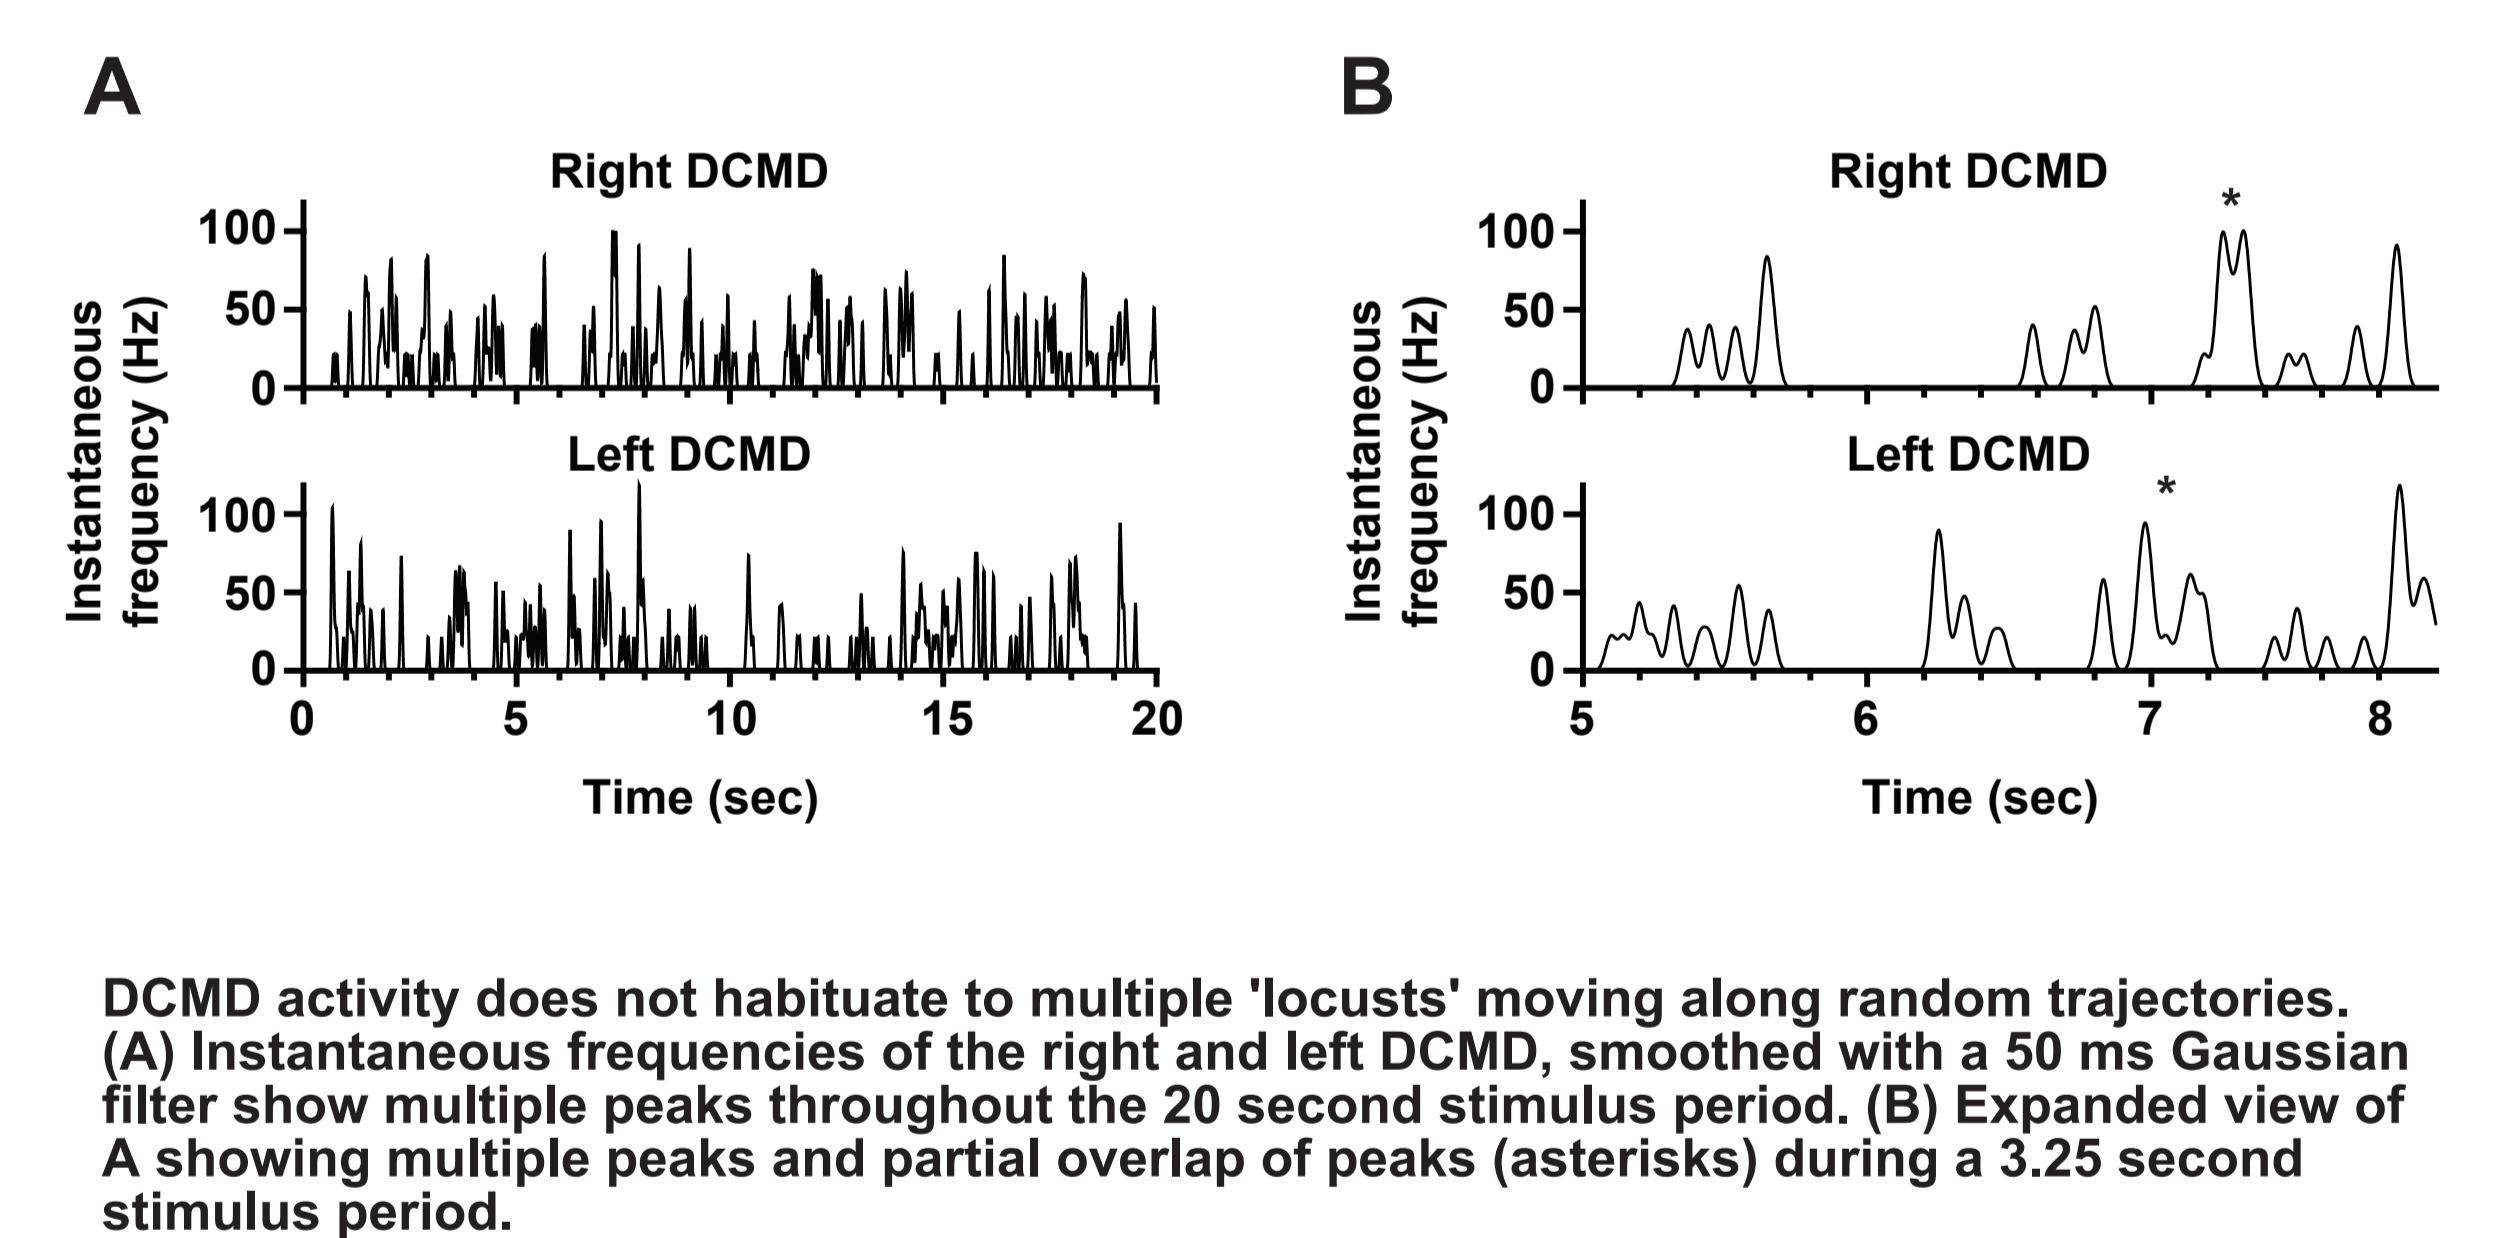

## 6 Peak time habituates to small lateral objects

## 7 Internal motion does not affect habituation

## 8 Responses to multiple objects

## Summary/Conclusions:

- Locust DCMDs were able to maintain 80% of the initial response to repeated approaches of a 'locust' or 'bird' presented at 30 second intervals.
- DCMD activity habituated to approximately 20% of the initial response during repeated approaches of a 'locust' or 'bird' at 0 second intervals.
- Habituated DCMDs were able to respond to an object approaching along a new trajectory or to a new, larger object.
- The time of DCMD peak firing habituates (occurs earlier) to small objects approaching along a lateral trajectory
- Internal motion of an approaching object does not affect habituation of the DCMDs.
- DCMDs do not habituate to multiple objects approaching along random trajectories.

These findings suggest that habituation to repeated looming stimuli may occur at specific synapses between upstream visual neurons and the LGMD. This localized habituation may function to allow locusts to remain vigilant to multiple objects in the natural environment.
